ABSTRACT

The chemical composition of West Kalimantan bauxite is 45 pct Al_2O_3 and 16 pct Fe_2O_3 that has been extracted to produce alumina and bauxite residue (red mud). The residues contains Al_2O_3 20 pct and Fe_2O_3 about 37 pct, wich was furthermore processed by roasting or lime-soda sinterization at temperature of 800-1100°C. The sintered product was leached with sodium carbonate solution to produce soluble sodium aluminate (2NaAlO_2). The solution obtained was then precipitated to produce hydrated alumina (Al(OH)_3). Hydrated alumina was then sulfateized by adding ammonium hydroxide, and followed by crystallization to produce high purity of ammonium aluminum sulfate crystals (alums). In addition, hydrated alumina was also chlorinated in stoichiometric amount at mol ratio of OH/Al = 0.5 – 1.5 to form polyaluminum chloride (PAC). The residue obtained from leaching was concentrated by 1000 gauss of magnetic separator to produce iron concentrate as a by product. As the results, sulfatation of hydrated alumina with addition of ammonium hydroxide results high grade of ammonium aluminum sulfate (NH_4Al(SO_4)_2 12H_2O) crystals. Chlorination of hydrated alumina in stoichiometric amount at mol ratio of OH/Al = 1.0 results polyaluminum chloride (PAC) that quality is adjacent to the first type of PAC. Through the soda-lime sinter process, it can also produce iron concentrate having grade of 66 % Fe_2O_3 with 40 % of recovery.

Keywords: bauxite residue, lime-soda sinter process, hydrated alumina, alums, PAC.

INTRODUCTION

Indonesia has potential bauxite resources, especially in West Kalimantan, Bintan island and surrounding of the area. West Kalimantan bauxite ore contains main compounds of Al_2O_3 44.79 %, Fe_2O_3 15.76 %, SiO_2 1.56 % and TiO_2 1.11 %. The processing of bauxite (Bayer Process) has been applied in producing alumina, however, the bauxite residue still contains significant Al_2O_3 20 % and Fe_2O_3 37 %.

Many ways have been tried and keep being developed for reusing bauxite residue by many countries which have alumina industries, one is Australia. In Australia, it is not less than 30 million ton of bauxite residue accumulates every year (40% from world production) [Sharif, 2005].

Research on extraction of alumina (Al_2O_3) from West Kalimantan bauxite residue was done by soda-lime sintering process that consists of sintering to the red mud with soda-lime at 800-1200°C resulting sintered sodium aluminate solution (2NaAlO_2). Separation of sodium aluminate solution from residue followed by precipitation of sodium aluminate solution result hydrated alumina (Al(OH)_3). Hydrated alumina can be used as a raw material (aluminum resources) for alums and polyaluminum chloride (PAC). Then the residue of solution can be concentrated by magnetic separator to result iron concentrate as a by product.

The aim of this research is to produce hydrated alumina from West Kalimantan bauxite residue by soda-lime sintering process as raw materials for making alums and poly aluminum chloride (PAC). It also results iron concentrate from residue of leaching as a by product. Alums and PAC was selected because these products are currently required for water treatment. As known that the community is often difficult to obtain clear water in dry season. Besides alums, Indonesia still imports PAC (in the form of hydrated alumina).
FUNDAMENTAL

Alumina

- Alumina from aluminosilicate minerals
  Padilla (1985) and Alp (2002) used lime-soda sinter process method to get alumina from aluminosilicate materials. In this process, aluminosilicate was reacted with lime (CaO) or calcium carbonate (CaCO₃) and sodium carbonate (Na₂CO₃) at high temperature (800-1200°C) to form sodium aluminate (Na₂O·Al₂O₃ or 2NaAlO₂) that is soluble in alkaline solution (Na₂CO₃ or NaOH) and to form dicalcium silicate (Ca₂SiO₄) which is not soluble in alkaline solution.

  The sintering reaction of clay materials can be stated as below [Padilla, 1985]:

  \[
  \text{Al}_2\text{Si}_2\text{O}_7 + \text{Na}_2\text{CO}_3 + 4\text{CaCO}_3 \rightarrow 2\text{NaAlO}_2 + 2\text{Ca}_2\text{SiO}_4 + 5\text{CO}_2 \quad \text{..................} (1)
  \]

- Alumina from aluminous ores and bauxite residue
  Aluminous ores (Al₂O₃) was reacted with Na₂CO₃ at temperature about 1000°C to form sodium aluminate. SiO₂ in aluminous ores causes sodium carbonate to react with SiO₂ during sintering process to form dissolved sodium silicate (Na₂SiO₃). The equation for that reaction [Habashi, 1997]:

  \[
  \text{Al}_2\text{O}_3 + \text{Na}_2\text{CO}_3 \rightarrow 2\text{NaAlO}_2 + \text{CO}_2 \quad \text{..................} (2)
  \]

  \[
  \text{SiO}_2 + \text{Na}_2\text{CO}_3 \rightarrow \text{Na}_2\text{SiO}_3 + \text{CO}_2 \quad \text{..................} (3)
  \]

  If sintered feed is added with CaO, sodium silicate will react with CaO and Al₂O₃ to form soluble sodium aluminate compound and unsoluble dicalcium silicate. The reaction is [Padilla, 1985]:

  \[
  \text{Na}_2\text{SiO}_3 + 2\text{CaO} + \text{Al}_2\text{O}_3 \rightarrow 2 \text{NaAlO}_2 + \text{Ca}_2\text{SiO}_4 \quad \text{..................} (4)
  \]

  Calcium can replace sodium to form calcium aluminate (3CaO·Al₂O₃) with chemical reaction [Habashi, 1997]:

  \[
  4\text{Al}_2\text{O}_3 + \text{Na}_2\text{CO}_3 + 3\text{CaO} \rightarrow 2\text{NaAlO}_2 + 3\text{CaO} \cdot \text{Al}_2\text{O}_3 + \text{CO}_2 \quad \text{..................} (5)
  \]

- Sinter Leaching
  Leaching of the sinter with sodium carbonate solution causes calcium aluminate to react with sodium carbonate to form sodium aluminate and solid residue of calcium carbonate (CaCO₃). [Habashi, 1997]:

  \[
  3\text{CaO} \cdot \text{Al}_2\text{O}_3 + 3\text{Na}_2\text{CO}_3 + \text{H}_2\text{O} \rightarrow 2\text{NaAlO}_2 + 4\text{NaOH} + 3\text{CaCO}_3 \quad \text{..................} (6)
  \]

Aluminum Sulfate Forming

Sulfatation of aluminum hydrate results aluminum sulfate, and sulfatation with adding ammonium hydroxide results ammonium aluminum sulfate.

  \[
  \text{Al(OH)}_3 + \text{H}_2\text{SO}_4 + \text{H}_2\text{O} \rightarrow \text{Al}_2(\text{SO}_4)\cdot18\text{H}_2\text{O} + \text{H}_2\text{O} \\
  \text{..........................} (7)
  \]

  \[
  \text{Al(OH)}_3 + \text{H}_2\text{SO}_4 + \text{H}_2\text{O} + \text{NH}_4\text{OH} \rightarrow \text{NH}_4\text{Al(ISO}_4)_2\cdot12\text{H}_2\text{O} + \text{H}_2\text{O} \quad \text{..................} (8)
  \]

  Ammonium aluminum sulfate solution can be crystallized in room temperature.

PAC FORMING

The mechanism of forming Poly Aluminum Chloride (PAC) can be explained by the reaction of AlCl₃ (aluminum chlorides) with Al(OH)₃ at mol ratio of OH/Al = 0.5 – 1.5 (Magnus, 1990). Aluminum chlorides are resulted through chlorination of Al(OH)₃. Furthermore, the reaction of AlCl₃ with Al(OH)₃ proceeds like ‘polymerization’ to form ‘poly aluminum chlorides’.

EXPERIMENTAL

Red mud from bauxite processing residue was prepared and mixed with CaO and Na₂CO₃ both in stoichiometric amount of 10 % excessive, it was formed as pellets and need to be dried. Sintering of the dried pellet was done at variation of the temperature of 800 - 1100 °C. Sintered product was leached in 2 % wt. of sodium carbonate solution at room temperature with agitation to get sodium aluminate solution (Na₂O·Al₂O₃). The solution was then separated from its residue by filtration, and the residue was washed with aquades twice. Filtrate and residue were analyzed by atomic adsorption spectrometry (AAS) for the chemical composition.
The chemical composition of residue, filtrate and washed filtrate were used to calculate the recovery of alumina. Hydrated alumina was added sulfuric acid and ammonium hydroxide to produce ammonium aluminum sulfate compound, and then was crystalized (Husaini, 2008). In addition, hydrated alumina was chlorinated with HCl to form AlCl₃, and then it was reacted by excess of hydrated alumina (polymerization) at mol ratio of OH/Al = 0.5 – 1.5 to form poly aluminum chloride. The residues of filtration was concentrated by magnetic separator (1000 Gauss) results iron concentrate as a by product, and it was analyzed by AAS for its chemical composition and recovery. Figure 1 shows the simplified scheme of the research.
RESULTS AND DISCUSSION

Bauxite Residue

Microscope optic examination shows a part of iron still interlock in gibsite particle (0.6 mm) and the other has already been liberated (Sutanto, 2008) shown in Figure 2.

Figure 2. Photomicrograph of bauxite; (a) a particle of gibsite (white) 0.6 mm interlock with iron particles (black), (b) a particle of gibbsite has already been liberated (white)

The chemical composition of West Kalimantan bauxite and its residue are shown in Tabel 1. Bauxite residue resulted from alumina extraction of bauxite ores by Bayer process still contains alumina 20% and iron 37%.

Sodium Aluminate Solution

Alumina was extracted from sinter by leaching with 2 % wt. of sodium carbonate solution. The result is shown in Figure 4. Sintering process in various temperature (800, 900, 1000, 1100°C) show that the highest amount of extracted alumina is 75% occured at 800°C with solid percentage of 11.8%. Between temperature of 900-1100°C, the extraction is downword to become 50% at 900°C and 45 % at 1100°C. The present results of leaching are more accurate than that of the last (Aziz, et.al., 2009) because the process used sodium carbonate solution 1 % wt. The present leaching however, uses 2 % wt. of sodium carbonate solution in order to leach as much as calcium from calcium aluminate compounds (3CaO.Al₂O₃) to form sodium aluminate solution (Alp, 2002).

Extracted alumina as function of sintering time is shown in Figure 5. Sintering temperature at 800°C results the highest extracted alumina of 85.20 %, occurred in ½ hours. However, within time interval of 1-4 hours the extraction tends to reduce. The alumina extraction is decreasing to become 47%

in 1 hour and 25% in 4 hours of the sintering time. The concentration of soluble main elements (Al⁺, Na⁺, Si⁺, Fe⁺, Ca⁺) in sodium aluminate solution is shown in Table 2.

The data show that sinter soda-lime process of bauxite residue produced sinter containing sodium aluminate (NaAlO₂) compound that is soluble in sodium carbonate solution, producing sodium aluminate (Na₂O.Al₂O₃) solution, and leaving the solid residue.

Precipitated Hydrated Alumina

Hydrated alumina was precipitated by carbonatation process. The chemical composition of hydrated alumina from precipitation of sodium aluminate solution and its anhydrated alumina after calcinations is shown in Table 3. The grade of alumina in hydrated alumina is 64.5 % Al₂O₃ and the anhydrated alumina from calcination contains 98.67 % Al₂O₃.

From above figures (Figure 6 & 7), we can see that all aluminum hydroxide has already changed to ammonium aluminum sulfate hydrate (alums) by sulfatation process. No iron detected in this alums, so that is physically shown of transparent alums. Husaini (2008) prepared alums who applied direct sulfatation of bauxite powder, however it produced brown colour of alums. The brown colour may be due to dissolved iron and other impurities from bauxite. This method needs next process after reducing the impurities from alums.

**Chlorination of Hydrated Alumina**

Hydrated alumina was chlorinated with HCl in stoichiometric amount to produce aluminum chloride (AlCl₃), then it was reacted by excess of hydrated alumina at mol ratio of OH/Al = 0.5 – 1.5 to form poly aluminum chloride (Al(OH)₁.₂ Cl₁.₈). Table 5 shows the products on chlorination of hydrated alumina at various mol ratio of OH/Al.

There are 2 (two) types of PAC in applications (Anonimous, 2010); the first type can be used for most applications, its contains Al₂O₃ 18-20 % (9.5-10.6 % Al) and Cl 21-22 %, the second type mostly uses for drinking water treatment, its contains Al₂O₃ 8.8-9.2 % (4.6-4.9 % Al) and Cl 9.8-11 %. The PAC resulted from this experiment (Code No.2) is considerably adjacent to the first type of PAC.

Figure 8 shows comparison floc setting time between experimental PAC (code-2) and imported PAC from Taki Chemicals, Japan. The figure shows that both of them have the same trend by pH, but experimental PAC resulted from this research has floc setting time little bit slower than that of imported one, it means that application of experimental PAC need more time to form floc and settle down to the bottom.

Iron Concentrate as By Product

Iron content in leached residue was separated by magnetic separator at intensity of 1000 gauss to produce iron concentrate 58-62 % Fe₂O₃. Table 6 shows the chemical composition of main compounds in iron concentrate. The value and recovery of Fe₂O₃ in iron concentrate for various sintering time were shown in Figure 9. At time interval of 1-4 hours, the iron content and recovery tend to decrease, the highest iron recovery (40 %) is occurred at ½ hours of sintering time. To get better result, the iron concentrate need to be upgraded by higher magnetic intensities.

CONCLUSION

– Amount of 75-85 % alumina could be recovered from bauxite residue by soda-lime sinter process at 800 °C, followed by leaching with sodium carbonate at room temperature.

– The highest extraction of alumina from bauxite residue is 85.20%, it is formed in such experimental condition (sintering temperature 800 °C, sintering time is ½ hours, leaching with 2 % wt. of sodium carbonate solution at room temperature, solid percentage is 11.8%, and agitation time is 2 hours). The value of alumina results up to 98.67 % Al₂O₃, it shows the same quality as imported alumina.

– Sintering temperature and time are very influenced to the recovery of alumina from bauxite residue. Higher sintering temperature would decrease the alumina extraction, and sintering time more than ½ hours reduces the extraction result.

Sulfatation of hydrated alumina with adding of ammonium hydroxide results in high grade of ammonium aluminum sulfate (NH₄Al(SO₄)₂.12H₂O) crystals.

Chlorination of hydrated alumina in stoichiometric amount at mol ratio of OH/Al = 1.0 results poly aluminum chloride (PAC) which is adjacent quality to the first type of PAC.

Through the soda-lime sinter process it can also produce iron concentrate having grade of 66 % Fe₂O₃ with 40 % of recovery.
